The Euler-Cauchy equation is often one of the first higher order differential equations with variable coefficients introduced in an undergraduate differential equations course. Putting a nonhomogeneous Euler-Cauchy equation on an exam in such a course, I was surprised when some of my students decided to apply the method of undetermined coefficients, which is guaranteed to work only for constant-coefficient equations, and obtained the correct answer! It turns out that we can find a particular solution to this equation using a substitution similar to the standard method of undetermined coefficients, if the right-hand side function is of a certain type, without using variation of parameters or transforming the equation to a constant-coefficient equation and then applying undetermined coefficients.

Such a solution is possible because of the fact, mentioned in many differential equations textbooks, that the Euler-Cauchy equation may be transformed by a change of variables into a constant-coefficient equation by simply defining $t = e^z$, if we assume $t > 0$. Thus, if the right-hand side function $f(t)$ is a monomial, then $f(e^z)$ is an exponential function; or if the right-hand side function $f(t)$ is the product of a monomial and a nonnegative integer power of $\ln(t)$, then $f(e^z)$ is the product of a monomial and an exponential function. And, since the new equation is a constant-coefficient equation, the method of undetermined coefficients can be applied, prescribing a solution that is an exponential function, in the first case, and the product of a polynomial and an exponential function in the second case. This leads to a method of undetermined coefficients for the original equation.

First, consider the second order Euler-Cauchy equation with a monomial right-hand side function,

$$t^2 y'' + at y' + by = At^\alpha, \; t > 0.$$  

(1)

If we suppose that $\alpha \in \mathbb{R}$ is not a root of the characteristic equation, then the above discussion indicates that we should try as our particular solution $y_p = Ct^\alpha$. Plugging $y_p$ into (1) gives

$$(\alpha(\alpha - 1) + a\alpha + b)Ct^\alpha = At^\alpha.$$  

Since we have assumed that $t > 0$ and $\alpha$ is not a root of the characteristic equation, we can solve directly for $C$.

But, what if $\alpha$ is, in fact, a root of the characteristic equation? As mentioned above, the Euler-Cauchy equation can be transformed into a constant-coefficient equation by means of the transformation $t = e^z$. This means that our first guess for the particular solution would be $y_p(z) = Ce^{\alpha z}$. But, since $\alpha$ is a root of the characteristic equation, we need to multiply by $z$
until $y_p(z)$ is no longer a solution to the complementary equation. Multiplication by $z$ in the guess for the particular solution for the transformed equation translates into multiplication by $\ln(t)$ in the particular solution for (1), suggesting a particular solution of the form of a constant multiple of $t^\alpha$ and a power of $\ln(t)$. We can verify by direct substitution that this is the correct form of the solution.

These ideas are summarized in the following theorem.

**Theorem 1.** For the second order Euler-Cauchy problem,

$$t^2 y'' + aty' + by = At^\alpha, t > 0,$$

where $\alpha \in \mathbb{R}$, a particular solution is of the form

(i) $y_p(t) = Ct^\alpha$, provided that $\alpha$ is not equal to any root of the characteristic equation, or

(ii) $y_p(t) = Ct^\alpha(\ln(t))^i$, if $\alpha$ is equal to a root of the characteristic equation, where $i$ is the multiplicity of the root.

For the more complicated equation

$$t^2 y'' + aty' + by = At^\alpha(\ln(t))^n, t > 0, \quad (2)$$

where $\alpha \in \mathbb{R}$ and $n$ is a nonnegative integer, a similar analysis leads to the following theorem.

**Theorem 2.** For the second order Euler-Cauchy problem,

$$t^2 y'' + aty' + by = At^\alpha(\ln(t))^n, t > 0,$$

where $\alpha \in \mathbb{R}$ and $n$ is a nonnegative integer, a particular solution is of the form

$$y_p(t) = (C_0 + C_1 \ln(t) + \ldots + C_n(\ln(t))^n) t^\alpha.$$

In fact, the above method will lead to a solution using undetermined coefficients for the following types of functions, as well:

(1) $A \cos(k \ln t)$ or $A \sin(k \ln t)$,

(2) $At^\alpha \cos(k \ln t)$ or $At^\alpha \sin(k \ln t)$, and

(3) $At^\alpha(\ln(t))^n \cos(k \ln t)$ or $At^\alpha(\ln(t))^n \sin(k \ln t)$.

You should, of course, verify this.

By the principle of superposition, the above results can be applied to Euler-Cauchy equations whose right-hand sides are sums of such functions, simply by applying the appropriate result to each term on the right-hand side. Here is an example.

**Example:** Find a general solution of $t^2 y'' - 4ty' + 4y = 4t^2(\ln(t))^2 - t, t > 0$.

- Complementary solution: Solve $t^2 y'' - 4ty' + 4y = 0$ to obtain $y_c = c_1 t + c_2 t^4$. 

• Particular solution: Find a solution of $t^2 y'' - 4ty' + 4y = 4t^2(\ln(t))^2 - t$.

The particular solution takes the form $y_p = y_{p1} + y_{p2}$. Since the first function is $4t^2(\ln(t))^2$, by Theorem ?? the first component of $y_p$, $y_{p1}$, is $(A + B(\ln(t)) + C(\ln(t))^2) t^2$. The particular solution corresponding to the second function, $t$, is determined using Theorem ??.

Since 1 is a simple root of the characteristic equation, the second component of $y_p$, $y_{p2}$, is $Dt \ln(t)$. So, $y_p = (A + B(\ln(t)) + C(\ln(t))^2) t^2 + Dt \ln(t)$. Plug $y_p$ into the differential equation, collect terms, and equate coefficients to obtain $A = -3, B = 2, C = -2$, and $D = \frac{1}{3}$, so

$$y_p = (-3 + 2 \ln(t) - 2(\ln(t))^2) t^2 + \frac{1}{3} t \ln(t).$$

General solution: $y = y_c + y_p$, so

$$y(t) = c_1 t + c_2 t^4 + (-3 + 2 \ln(t) - 2(\ln(t))^2) t^2 + \frac{1}{3} t \ln(t).$$

It is straightforward to generalize the approach described in this paper to higher order Euler-Cauchy equations.
